

# Survey of Graph Database Models

RENZO ANGLES and CLAUDIO GUTIERREZ

Computer Science Department, Universidad de Chile

---

Graph database models can be characterized as those where data structures for the schema and instances are modeled as graphs or generalizations of them, and data manipulation is expressed by graph-oriented operations and type constructors. These models flourished in the eighties and early nineties in parallel to object oriented models and their influence gradually faded with the emergence of other database models, particularly the geographical, spatial, semistructured and XML.

Recently, the need to manage information with inherent graph-like nature has brought back the relevance of the area. In fact, a whole new wave of applications for graph databases emerged with the development of huge networks (*e.g.* Web, geographical systems, transportation, telephones), and families of networks generated due to the automation of the process of data gathering (*e.g.* social and biological networks).

The main objective of this survey is to present in a single place the work that has been done in the area of graph database modeling, concentrating in data structures, query languages and integrity constraints.

Categories and Subject Descriptors: G.2.2 [**Discrete Mathematics**]: Graph Theory—*graph algorithms; networks problems*; H.2.1 [**Database Management**]: Logical Design—*data Models*; H.2.3 [**Database Management**]: Languages—*data description languages (DDL); data manipulation languages (DML); query Languages*; H.2.5 [**Database Management**]: Heterogeneous Databases; H.2.8 [**Database Management**]: Applications; I.2.4 [**Artificial Intelligence**]: Knowledge Representation Formalisms and Methods—*representation languages; semantic networks*; K.6.3 [**Management of Computing and Information Systems**]: Software Management—*Software development*

General Terms: Design, Languages, Management

Additional Key Words and Phrases: Conceptual database models, database systems, database models, graph databases, graph database models, graph query languages, graph integrity constraints

---

## 1. INTRODUCTION

The term data model has been used in the information management community with different meanings and in diverse contexts. In its most general sense, a data[base] model (*db-model*)<sup>1</sup> is a concept that describes a collection of conceptual tools for representing real-world entities to be modeled and the relationships among these entities [Silberschatz et al. 1996]. Often this term denotes simply a collection of data structure types, or even a mathematical framework to represent knowledge [McGee 1976].

From a database point of view, the conceptual tools defining a db-model should address at least the structuring and description of the data, its maintainability and the form to retrieve or query the data. According to these criteria, a db-model is defined as a combination of three components, first a collection of data structure

---

<sup>1</sup>In the database literature the terms “data model” and “database model” (and sometimes even “model”) usually denote the same concept. In the scope of this survey we will consider them as synonyms and use the abbreviated expression db-model.

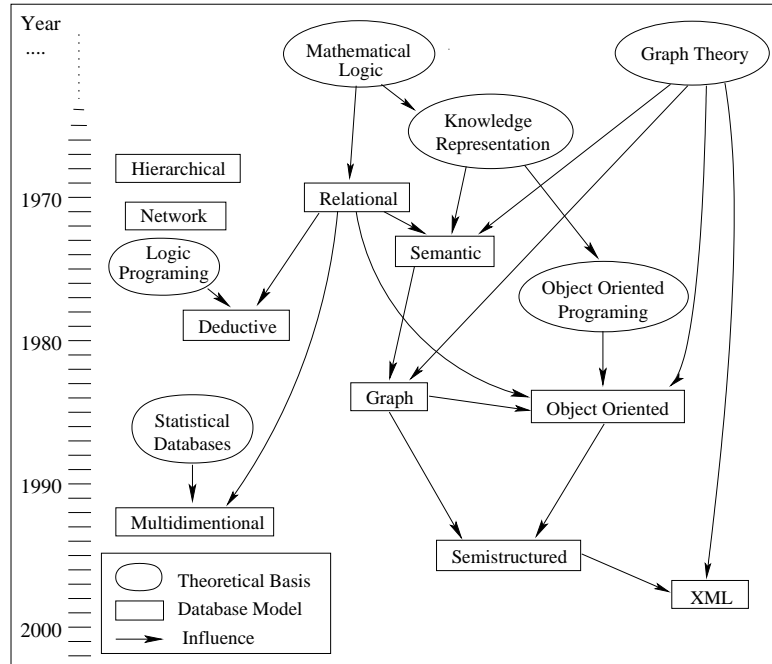

Fig. 1. Evolution of database models. Rectangles denote database models, arrows indicate influences, and circles denote theoretical developments. On the left hand side a time-line in years (After a diagram by A. O. Mendelzon.)

types, second a collection of operators or inference rules and third a collection of general integrity rules [Codd 1980]. Note that several proposals of db-models define only the data structures, omitting sometimes operators and/or integrity rules.

Due to the importance of modeling conceptually, philosophically and in practice, db-models have become essential abstraction tools. Among the purposes of a db-model are: tool for specifying the kinds of data permissible; general design methodology for databases; coping with evolution of databases; development of families of high level languages for query and data manipulation; focus in DBMS architecture; vehicle for research into the behavioral properties of alternative organizations of data [Codd 1980].

Since the emergence of database management systems, there has been an ongoing debate about what the db-model for such a system should be. The evolution and diversity of existent db-models show that there is no silver bullet for data modeling. The parameters influencing their development are manifold, and among the most important we can mention the characteristics or structure of the domain to be modeled, the type of intellectual tools that appeals the user, and of course, the hardware and software constraints imposed. Additionally, each db-model proposal is grounded on certain theoretical tools, and serves as base for the development of related models. Figure 1 sketches these influences.

Surveys and taxonomies of db-models are as manifold as db-models themselves (e.g. [Silberschatz et al. 1996; Navathe 1992; Beeri 1988; Kerschberg et al. 1976]).

Following we briefly describe the most representative and widely accepted and/or used db-models which are of general purpose, *i.e.*, although best suited for particular kinds of data, do not have any particular application in mind.

### 1.1 Database Models Evolution – Brief Historical Overview

In the beginnings of the design of db-models, physical (hardware) constraints were one of the fundamental parameters to be considered. Before the advent of the relational model, most db-model focused essentially in the specification of the structure of data in actual file systems. Kerschberg et al. [1976] developed a taxonomy of db-models prior to 1976, comparing essentially their mathematical structures and foundation, and the levels of abstraction used.

Two representative db-models are the *hierarchical* [Tsichritzis and Lochovsky 1976] and *network* [Taylor and Frank 1976] models, which emphasize the physical level, and offer the user the means to navigate the database at the record level, thus providing low level operations to derive more abstract structures.

The *relational db-model* was introduced by Codd [1970; 1983] and highlights the concept of level of abstraction by introducing the idea of separation between physical and logical levels. It is based on the notions of sets and relations. Due to its simplicity of modeling, it gained a wide popularity among business applications.

*Semantic db-models* [Peckham and Maryanski 1988] allow database designers to represent objects and their relations in a natural and clear manner to the user (as opposed to previous models). They intended to provide the user with tools that could capture faithfully the semantics of the information to be modeled. A well-known example is the entity-relationship model [Chen 1976].

*Object oriented db-models* [Kim 1990] appeared in the eighties, when most of the research was concerned with so called “advanced systems for new types of applications [Beerli 1988]”. These db-models are based on the object-oriented paradigm and their goal is representing data as a collection of objects that are organized in classes and have complex values associated with them.

*Graph db-models* made their appearance almost in parallel with the object oriented db-models, as an alternative to the limitations of traditional db-models for capturing the inherent graph structure of data appearing in applications such as hypertext or geographic database systems, where the interconnectivity of data is an important aspect.

*Semistructured db-models* [Buneman 1997] are designed to model data with a flexible structure, *e.g.*, documents and Web pages. Semistructured data (also called unstructured data) is neither raw nor strictly typed as in conventional database systems. Additionally, data is mixed with the schema, a feature which allows extensible exchange of data. These db-models appeared in the nineties and are currently in evolution.

The *XML (eXtensible Markup Language)* [Bray et al. ] model did not originate in the database community. Although originally introduced as a standard to exchange and model documents, soon it became a general purpose model, with focus on information with tree-like structure. Similar to semistructured model, schema and data are mixed.

See Section 2.3 for a more in depth comparison among these models.

## 1.2 Scope, Contributions and Organization of this Survey

The objective of this survey is to present in a single place the work that has been done in the area of graph database modeling. On these lines, the survey is slightly biased towards sistematizing the different developments and relevant pointers to facilitate researchers to go to the sources, rather than balancing the area. This goal is highlighted by the fact that the area has been overlooked and lately is gaining relevance again.

The contributions of this survey are:

- To conceptualize the notion of graph db-model by proposing a definition which encompasses implicit and informal notions used in the literature (Section 2.1).
- To compare graph db-models against other db-models, highlighting their importance as an area with its own motivations, applications and characteristic problems (Sections 2.2, 2.3 and 2.4).
- To define a set of typical characteristics of graph db-models and do a comparative study of existing graph db-models based on this criteria. We concentrate in presenting the main aspects of modeling, that is, data structures, query languages and integrity constraints (Section 3).
- To present in a single place a working description of the most relevant graph db-models (Appendix A).

We would like to warn the reader that there are several related topics that fall out of the scope of this survey. Among the most important we can mention graph visualization, graph data structures and algorithms for secondary memory, graph methods for databases, and in general graph database system implementation.

On the same lines, there are other important db-models as well as modeling frameworks which concern graph modeling, but due to the size limitations of this survey they are not covered here. Among the db-models are Spatial db-models [Paredaens and Kuijpers 1998; Samet and Aref 1995], Geographical Information Systems (GIS) [Shekhar et al. 1997; Aaufaure-Portier and Trépied 1976], Temporal db-models [Tansel et al. 1993; Chomicki 1994], and Multidimensional db-models [Vassiliadis and Sellis 1999]. Frameworks related to our topic, but not directly focusing in database issues are Semantic Networks [Sowa 1991; Griffith 1982], Conceptual Graphs [Sowa 1976; 1984], Knowledge Representation Systems [Deng and Chang 1990], Topic Maps [Pepper and Moore 2001; ISO 1999], Hypertext [Conklin 1987], and the recent family of models for representing ontologies on the Web, OWL [McGuinness and van Harmelen 2004].

## 2. GRAPH DATA MODELING

### 2.1 What is a Graph Data Model?

Although most papers on graph db-models use the term “graph data[base] model”, few of them define the notion explicitly. Nevertheless their views on what a graph db-model is do not differ substantially. In some cases an implicit definition is given as a comparison against other models where graphs are involved, like the semantic, object-oriented and semi-structured models.

In what follows we will conceptualize the notion of graph db-model based on three

basic components, namely data structures, transformation language, and integrity constraints. Hence, a graph db-model is characterized by:

— *The data and/or the schema are represented by graphs*, or by data structures generalizing the notion of graph (hypergraphs or hypernodes). There is wide consensus on this point modulo slight variations.

Let us review different wordings of authors on this issue. The approach is to model the database directly and entirely as a graph [Güting 1994]. A graph db-model is one whose single underlying data structure is a labeled directed graph; the database consists of a single digraph [Levene and Loizou 1995]. A database schema in this model is a directed graph, where leaves represent data and internal nodes represent connections between the data [Kuper and Vardi 1984]. Directed labeled graphs are used as the formalism to specify and represent database schemas, instances, and rules [Paredaens et al. 1995]. In this model, a database is described in terms of a labeled directed graph called schema graph [Kunii 1987]. A graph db-model formalizes the representation of the data structures stored in the databases as a graph [Graves et al. 1995a]. The schema as well as the instance of an object database is represented by a graph. The nodes of the instance represent the objects of the database [Gyssens et al. 1990]. Database instances and database schemas are described by certain types of labeled graphs [Hidders 2002]. The model for data is organized as graphs [Amann and Scholl 1992]. Labeled graphs are used to represent schemas and instances [Hidders and Paredaens 1993].

An issue transversal to all graph db-models is the level of separation between schema and data (instances). In most cases the schema and the instances can be clearly distinguished.

— *Data manipulation is expressed by graph transformations* [Gyssens et al. 1990], or by operations whose main primitives address directly typical features of graphs, like paths, neighborhoods, subgraphs, graph patterns, connectivity, and statistics about graphs (diameter, centrality, etc.). The db-model defines a flexible collection of type constructors and operators which create and access the graph data structures [Graves et al. 1995a], or in other terms, the approach is to express all queries in terms of a few powerful graph manipulation primitives [Güting 1994]. The operators of the language can be based on pattern matching, *i.e.* finding of all occurrences of a prototypical piece of an instance graph [Hidders and Paredaens 1993].

— The existence of *integrity constraints* enforcing the consistency of the data. These constraints can be grouped in schema-instance consistency, identity and referential integrity, and functional and inclusion dependencies. Examples of these are, labels with unique names [Graves et al. 1995b], typing constraints on nodes [Kuper and Vardi 1993], functional dependencies [Levene and Poulouvasilis 1991], domain and range of properties [Klyne and Carroll 2004].

Summarizing, a graph db-model is a model where the data structures for the schema and/or instances are modeled as a (labeled)(directed) graph, or generalizations of the graph data structure, where data manipulation is expressed by graph-oriented operations and type constructors, and has integrity constraints appropriate for the graph structure.

Table I. A coarse-granularity comparative view among the most influential database models. The parameters are: abstraction level, base data structure used, and the types of information objects the db-model focus in.

Database model	Abstraction level	Base data structure	Information focus
Network	physical	pointers + records	records
Relational	logical	relations	data + attributes
Semantic	user	graph	schema + relations
Object oriented	physical/logical	objects	object + methods
Semistructured	logical	tree	data + components
Graph	logical/user	graph	data + relations

## 2.2 Why a Graph Data Model?

The application areas of graph db-models are those where information about the interconnectivity or the topology of the data is more important, or as important as, the data itself. This is usually accompanied by the fact that data and relations among data are at the same level. In fact, introducing graphs as a modeling tool has several advantages for this type of data.

First, it leads to a more natural modeling. Graph structures are visible to the user and they allow a natural way of handling applications data (*e.g.* hypertext or geographic databases). Graphs have the advantage of being able to keep all the information about an entity in a single node and show related information by arcs connected to it [Paredaens et al. 1995]. Graph objects (like paths, neighborhoods) may have first order citizenship; a user can define some part of the database explicitly as a graph structure [Güting 1994], allowing encapsulation and context definition [Levene and Poulouvasilis 1990].

Second, queries can refer directly to this graph structure. Associated with graphs are specific graph operations in the query language algebra, such as finding shortest paths, determining certain subgraphs, and so forth. Explicit graphs and graph operations allow users to express a query at a high level of abstraction. To some extent, this is in contrast to graph manipulation in deductive databases, where often fairly complex rule programs need to be written [Güting 1994]. It is not important to require full knowledge of the structure to express meaningful queries [Abiteboul et al. 1997]. Last but not least, for purposes of browsing it may be convenient to forget the schema [Buneman et al. 1996].

Third, as far as implementation is concerned, graph databases may provide special structures for the storage of graphs and efficient graph algorithms available for realizing specific operations [Güting 1994].

## 2.3 Comparison with other Database Models

In this section we compare graph db-models with the most influential db-models. Table I presents a coarse granularity overview of these comparison. Below we present the details.

*Physical db-models* were the first ones to offer the possibility to organize large collections of data. Among the most important ones are the hierarchical [Tsichritzis and Lochovsky 1976] and network [Taylor and Frank 1976] models. These models lack good abstraction level and are close to physical implementations. The data-structuring is not flexible and not apt to model non-traditional applications.

*Relational db-model* [Codd 1970; 1983] was introduced by Codd to highlight the concept of level of abstraction by introducing a separation between physical and logical levels. Gradually the focus shifted to modeling data as seen by applications and users [Navathe 1992]. This is the emphasis and the achievement of the relational model, in a time where the domain of application were basically simple data (banks, payments, commercial and administrative applications).

The relational model was a landmark development because it provided a mathematical basis to the discipline of data modeling. It is based on the simple notion of relation, which together with its associated algebra and logic, made the relational model a primary model for database research. In particular, its standard query and transformation language, SQL, became a paradigmatic language for querying.

The differences between graph db-models and the relational db-model are manifold. Among the most relevant ones are: the relational model was directed to simple record-type data with a structure known in advance (airline reservations, accounting, inventories, etc.). The schema is fixed and extensibility is a difficult task. Integration of different schemas is not easy nor automatizable. The query language is not oriented to explore the underlying graph of relationships among the data, for example paths, neighborhoods, patterns.

*Semantic db-models* [Peckham and Maryanski 1988] have their origin in the necessity to provide more expressiveness and to incorporate a richer set of semantics into the database from the user point of view. They allow database designers to represent objects and their relations in a natural and clear manner (similar to the way users view an application) by using high-level abstraction concepts such as aggregation, classification and instantiation, sub- and super-classing, attribute inheritance and hierarchies [Navathe 1992].

In general, the advantages of semantic models, are oriented toward the support of database design and evolution [Hull and King 1987]. A well-known example is the entity-relationship model [Chen 1976]. It has become a basis for the early stages of database design. Other examples of semantic db-models are IFO [Abiteboul and Hull 1984] and SDM [Hammer and McLeod 1978]. For graph db-models research, semantic db-models are relevant because their orientation to deal with problem associated to graph structure and relations among the entities to be modeled.

*Object oriented (O-O) db-models* [Kim 1990] appeared in the eighties, when the database community realized that the relational model was inadequate for data intensive domains (Knowledge bases, engineering applications). O-O databases were motivated by the emergence of non-conventional database applications consisting of complex objects systems with many semantically interrelated components as in CAD/CAM, computer graphics or information retrieval.

According to the O-O programming paradigm on which they are based, their objective is to represent data as a collection of objects that are organized in classes and have complex values and methods associated with them. Although O-O db-models permit much richer structures than the relational db-model, they still require that all data conform to a predefined schema [Abiteboul et al. 1997].

O-O db-models are similar to semantic models in that they provide mechanisms for constructing complex data by interrelating objects, and are fundamentally different in that they support forms of local behavior in a manner similar to object-

oriented programming languages. For example, in O-O db-models identifiers are external to the objects and they remain invariant, whereas semantic models make up identifiers or keys based on internal attributes or internal properties; O-O support information-hidding and encapsulation [Navathe 1992].

O-O db-models have been related to graph db-models due to the explicit or implicit graph structure in their definitions [Levene and Poulouvasilis 1991; Andries et al. 1992; Gyssens et al. 1990]. Nevertheless, there remain important differences rooted in the form that each of them models the world. O-O db-models view the world as a set of complex objects having certain state (data) and interacting among them by methods. On the contrary, graph db-models, view the world as a network of relations, emphasizing the interconnection of the data, and the properties of these relations.

The emphasis of O-O db-models is on the dynamics of the objects, their values and methods. In contrast, graph db-models emphasizes the interconnection while maintaining the structural and semantic complexity of the data. Further comparison between O-O and graph db-models may be founded in [Beeri 1988; Kerschberg et al. 1976; Navathe 1992; Silberschatz et al. 1996].

*Semistructured db-models* [Buneman 1997; Abiteboul 1997] were motivated by the increased existence of semistructured data (also called unstructured data), data exchange, and data browsing [Buneman 1997]. In semistructured data the structure is irregular, implicit and partial; the schema does not restrict the data, only describes it, is very large and rapidly evolving; the information associated with a schema is contained within the data (data contains data and its description, so it is self-describing) [Abiteboul 1997].

Among the most representative models are OEM [Papakonstantinou et al. 1995], Lorel [Abiteboul et al. 1997], UnQL [Buneman et al. 1996], ACeDB [Stein and Tierry-Mieg 1999] and Strudel [Fernández et al. 1998]. Generally, semistructured data is represented by a tree-like structure. Nevertheless cycles between data are possible, establishing in this way a structural relation with graph db-models. Some authors characterize semistructured data as rooted directed connected graphs [Buneman et al. 1996].

## 2.4 Graph Data Models Motivations and Applications

Graph db-models are motivated by real-life applications where information about interconnectivity of its pieces is a salient feature. We will divide these application areas into Classical and Complex networks.

*Classical Applications.* The applications that motivated the introduction of the notion of graph databases were manifold:

- Generalizations of classical db-models [Kuper and Vardi 1984]. Classical models were criticized for their lack of semantics, the flat structure of the data they allow, the difficulties for the user to “see” the connectivity of the data, and the difficult to model complex objects [Levene and Poulouvasilis 1990].
- On the same direction, the observation that graphs have been integral part of the database design process in semantic and object-oriented db-models, brought the idea of introducing a model in which both, data manipulation and data representation were graph based [Gyssens et al. 1990].

- Limitations of expressive power of languages for complex applications motivated also the search for models that resemble more closely such applications [Paredaens et al. 1995].
- Limitations (at the time) of knowledge representation systems [Kunii 1987], and the need for intricate but flexible knowledge representation and derivation techniques [Paredaens et al. 1995].
- The need for improving functionalities of object-oriented db-models [Poulovassilis and Levene 1994]. In this direction the application in mind were CASE, CAD, image processing, and scientific data analysis.
- Graphical and visual interfaces, geographical, pictorial and multimedia systems [Gyssens et al. 1990; Consens and Mendelzon 1993; Sheng et al. 1999].
- Applications where data complexity exceeded the relational db-model capabilities also motivated graph databases. For instance, managing transport networks (train, plane, water, telecommunications) [Mainguenaud 1995], spatially embedded networks like highway, public transport [Güting 1994]. Several of these applications are now in the field of GIS and spatial databases.
- Software systems and integration [Kiesel et al. 1996].
- The emergence of hypertext on-line made evident the need for other db-models, for example [Tompa 1989; Watters and Shepherd 1990; Amann and Scholl 1992]. Together with hypertext, the Web created the need for a model more apt than classical ones for information exchange.

*Complex Networks.* Several areas have witnessed the emergence of huge networks of data which share some particular mathematical parameters, called complex networks [Newman 2003; Albert and Barabasi 2002; Dorogovtsev and Mendes 2003]. The need for database management for some classes of these networks has been recently highlighted [Olken 2003; Jagadish and Olken 2003; Tsvetovat et al. 2004; Graves et al. 1995b]. Although it is not evident yet if from the point of view of databases one can treat them as a whole, we will describe them together for presentation purposes. After the survey of Newman [2003], we will group them in four categories: social networks, information networks, technological networks and biological networks. Following we describe specific examples for each of them.

- In *social networks* [Hanneman 2001], nodes are people and groups while links show relationships or flows between the nodes. Some examples are friendship, business relationships, patterns of sexual contacts, research networks (collaboration, co-authorship), communication records (mail, telephone calls, email), Computer networks [Wellman et al. 1996], National security [Sheth et al. 2005]. There is growing activity in the area of Social Network analysis [Brandes 2005], visualization and data processing in such networks.
- Information networks* model relations representing information flow, such as citations between academic papers [de S. Price 1965], World Wide Web (hypertext, hypermedia) [Florescu et al. 1998; Kumar et al. 2000; Broder et al. 2000], peer-to-peer networks [Nejdl et al. 2003], relations between word classes in a thesaurus, preference networks.
- In *technological networks* the structure is mainly governed by space and geography. Some examples are Internet (as network of computers), electric power

grids, airline routes, telephone networks, delivery network (post office). The area of *Geographic Information Systems (GIS)* is today covering a big part of this area (roads, railways, pedestrian traffic, rivers) [Shekhar et al. 1997; Medeiros and Pires 1994].

—*Biological networks* represent biological information whose volume, management and analysis has become an issue due to the automation of the process of data gathering. Good example is the area of *Genomics*, where networks occur in gene regulation, metabolic pathways, chemical structure, map order and homology relationships between species [Graves]. There are other kinds of biological networks, such as food webs, neural networks, etc. The reader can consult database proposals for genomics [Graves et al. 1995b; Graves; Hammer and Schneider 2004], an overview of models for biochemical pathways [Deville et al. 2003], a tutorial on Graph Data Management for Biology [Olken 2003], and a model for Chemistry [Benkő et al. 2003].

It is important to stress that classical query languages offer little help when dealing with the type of queries needed in the above areas. As examples, data processing in GIS include geometric operations (area or boundary, intersection, inclusions, etc), topological operations (connectedness, paths, neighbors, etc) and metric operations (distance between entities, diameter of the network, etc). In genetic regulatory networks examples of measures are connected components (interactions between proteins) and degrees of nearest neighbors (strong pair correlations). In social networks, distance, neighborhoods, clustering coefficient of a vertex, clustering coefficient of a network, betweenness, size of giant connected components, size distribution of finite connected components [Dorogovtsev and Mendes 2003]. Similar problems arise in the Semantic Web, where querying RDF data increasingly needs graph features [Angles and Gutierrez 2005].

### 3. GRAPH DATABASE MODELS

This section presents the work that has been done in the database community on graph db-models. We start by presenting a brief historical overview of the main developments in the area in the form of proposals of graph db-models. Then, we proceed to a comparative study of the main features of graph db-models.

Database models are typically compared by either using a set of common features [Fry and Sibley 1976; Tschritzis and Lochovsky 1976; Peckham and Maryanski 1988] or defining a general model used as comparison basis [Hull and King 1987]. The evaluation presented in this survey follows a conceptual organization of modeling features, by considering three general components in the database modeling process: (a) Basic foundations of the model and the data structures available at schema and instance level, (b) Approaches to enforce data consistency (integrity constraints), and (c) Languages for querying and manipulating the database. The study emphasizes conceptual modeling issues rather than implementation aspects. Figure 4 summarizes the set of features and other information about graph db-models.

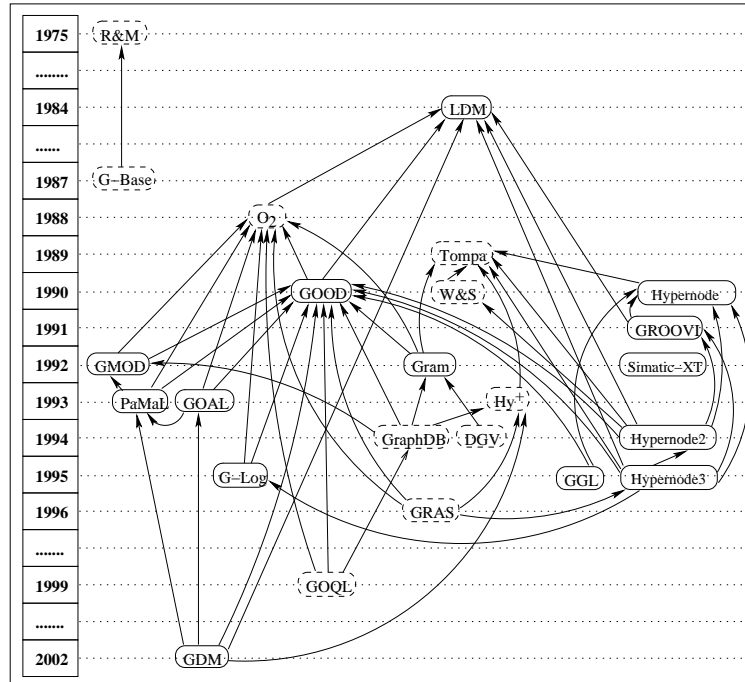

Fig. 2. Graph db-models development. Nodes indicate models and arrows citations. Dashed nodes represent related works in graph db-models. DGV [Gutiérrez et al. 1994], GDM [Hidders 2002], GGL [Graves et al. 1995a], GMOD [Andries et al. 1992], GOAL [Hidders and Paredaens 1993], GOOD [Gyssens et al. 1990; 1991], GOQL [Sheng et al. 1999], Gram [Amann and Scholl 1992], GRAS [Kiesel et al. 1996], GraphDB [Gütting 1994], GROOVY [Levene and Poulouvasilis 1991], G-Base [Kunii 1987], G-Log [Paredaens et al. 1995], Hypernode [Levene and Poulouvasilis 1990], Hypernode2 [Poulouvasilis and Levene 1994], Hypernode3 [Levene and Loizou 1995], Hy+ [Consens and Mendelzon 1993], LDM [Kuper and Vardi 1984; 1993], O<sub>2</sub> [Lécluse et al. 1988], PaMaL [Gemis and Paredaens 1993], R&M [Roussopoulos and Mylopoulos 1975], Simatic-XT [Mainguenaud 1992], Tompa [Tompa 1989], W&S [Watters and Shepherd 1990].

### 3.1 Brief Historical Overview

Activity around graph databases flourished in the first half of the nineties and then the topic almost disappeared. The reasons for this decline are manifold: the database community moved toward semistructured data (a research topic which did not have links to the graph database work in the nineties); the emergence of XML captured all the attention of the work on hypertext; people working on graph databases moved to particular applications like spatial data, web, documents; the tree-like structure is enough for most applications. Figure 2 reflects this evolution by means of papers published in main conferences and journals.

Graph db-models emerged with the objective of modeling information whose structure is a graph. In an early approach, Roussopoulos and Mylopoulos [1975] facing the failure of current (at the time) systems to take into account the semantics of the database, proposed a semantic network to store data about the database. An implicit structure of graphs for the data itself was presented in the Functional Data

Model [Shipman 1981], whose goal was to provide a “conceptually natural” database interface. A different approach proposed the Logical Data Model (LDM) [Kuper and Vardi 1984], where an explicit graph db-model intended to generalize the relational, hierarchical and network models. Years later Kunii [1987] proposed a graph db-model for representing complex structures of knowledge called G-Base.

In the late eighties, Lécluse et al. [1988] introduced  $O_2$ , an object oriented db-model based on a graph structure. On the same lines, GOOD [Gyssens et al. 1990] is an influential graph-oriented object model, intended to be a theoretical basis for a system in which manipulation as well as representation are transparently graph-based. Among the subsequent developments based on GOOD are: GMOD [Andries et al. 1992] that proposes a number of concepts for graph-oriented database user interfaces; Gram [Amann and Scholl 1992] which is an explicit graph db-model for hypertext data; PaMaL [Gemis and Paredaens 1993] which extends GOOD with explicit representation of tuples and sets; GOAL [Hidders and Paredaens 1993] that introduces the notion of association nodes; G-Log [Paredaens et al. 1995] which proposed a declarative query language for graphs; and GDM [Hidders 2002] that incorporates representation of n-ary symmetric relationships.

There were proposals that used generalization of graphs with data modeling purposes. Levene and Poulouvasilis [1990] introduced a db-model based on nested graphs, called the Hypernode Model, on which subsequent work was developed [Poulouvasilis and Levene 1994; Levene and Loizou 1995]. The same idea was used for modeling multi-scaled networks [Mainguenaud 1992] and genome data [Graves et al. 1995a]. GROOVY [Levene and Poulouvasilis 1991] is an object oriented db-model which is formalized using hypergraphs. This generalization was used in other contexts: query and visualization in the Hy+ system [Consens and Mendelzon 1993]; modeling of data instances and access to them [Watters and Shepherd 1990]; representation of user state and browsing [Tompa 1989];

There are several other proposals that deal with graph data models. Güting proposed GraphDB [Güting 1994] intended for modeling and querying graphs in object-oriented databases and motivated by managing information in transport networks. Database Graph Views [Gutiérrez et al. 1994] proposed an abstraction mechanism to define and manipulate graphs stored in either relational object oriented or file systems. The project GRAS [Kiesel et al. 1996] uses attributed graphs for modeling complex information from software engineering projects. The well known OEM [Papakonstantinou et al. 1995] model aims at providing integrated access to heterogeneous information sources, focusing in information exchange. Another important and recent line of development has to do with data representation models and the World Wide Web. Among them are data exchange models like XML [Bray et al. ], metadata representation models like RDF [Klyne and Carroll 2004] and ontology representation models like OWL [McGuinness and van Harmelen 2004].

### 3.2 Data Structures

The representation of entities and relations are identified as being fundamental to graph db-models. An entity or object represents something that exists as a single and complete unit. A relation is a property or predicate that establishes a connection between two or more entities. In this section, we analyze the data structures used for modeling entities and relations in graph db-models.

One of the most distinctive characteristic of a graph db-model is a framework for the representation of connectivity among entities, distinct from attributes (relational model), standard abstractions (semantic models), complex objects (O-O models), or composition relations (semistructured models).

All graph db-models have as their formal foundation variations on the basic mathematical definition of a graph, e.g. directed or undirected graphs, labeled or unlabeled edges and nodes, hypergraphs, hypernodes. On top of this basic layer, models present diverse features influenced by the semantic or object oriented approaches. For example, the data representation of GOOD, GMOD, G-Log and Gram is simply a digraph with labeled nodes and labeled edges between them. The Hypernode Model, Simatic-XT and GGL emphasize the use of hypernodes for representing nested complex objects. GROOVY is centered in the use of hypergraphs as a formalism for modeling complex objects, sub-object sharing, integrity constraints and structural inheritance.

Representing the database as a simple flat graph (with many interconnected nodes) has the drawback that, in practice, it is difficult to present the information to the user in a clear way. In contrast, a hypernode database consists of a set of nested graphs, which provides inherent support for data abstraction and the ability to represent each real-world object as a separate database entity [Poulovassilis and Levene 1994]. Additionally, the use of hypernodes and hypergraphs allows a concept to grow from a simple undefined concept (primitive object) to one defined by multiple complex relations (complex object). In contrast, a pure-graph approach (where nodes and edges are different structures) does not provide such expressiveness and extensibility.

Note that, hypergraphs can be modeled by hypernodes by (i) encapsulating the contents of each undirected hyperedge within a further hypernode and (ii) replacing each directed hyperedge by two hypernodes related by a labeled edge. In contrast, multi-level nesting provided by hypernodes cannot be easily captured by hypergraphs.

Most models have explicit labels on edges, except LDM, GROOVY and the Hypernode model. LDM has an order among the edges which induce implicit labeling. The Hypernode model and GROOVY do not use labeled edges but the task of representing relations (and its names) can be attained by encapsulating edges which represent the same relation (same label edges), within one hypernode (or hyperedge) labeled with the relation-name. For example, we can represent the set of labeled arcs  $person1 \xrightarrow{name} George$ ,  $person2 \xrightarrow{name} Ana$  and  $person3 \xrightarrow{name} Julia$ , by the hypernode:

Next, we will study in more detail the representation of entities and relations.

**3.2.1 Representation of entities.** Models represent entities at both, instance and schema level. Specifically, entity types, relation types and schema restrictions are related to the definition of the database schema, and instances of entities and relations conform the database instances.

Several models (e.g. GOOD, GMOD, G-Log and Gram) represent both schema and instance as a labeled digraph. An exception is LDM, whose schemas are digraphs where leaves represent data and internal nodes represent structured data. LDM instances consist of two-column tables, each of which associates entities of a particular type (primitive, tuple or set).

A *schema* graph defines: (a) *entity types* represented as nodes labeled with zero (GMOD) or one type name; (b) *primitive entities* represented as nodes labeled with basic types; and (c) *relations* represented as edges labeled with relation-names. Relations are only defined for entity types (primitive entities have no properties) and each primitive entity has an associated domain of constants.

An *instance* graph contains: (a) *concrete entities* represented as nodes labeled by either an entity type name or an object identifier; (b) *primitive values* represented as nodes labeled with a value from the domain of a primitive entity; and (c) relations represented as edges labeled with the corresponding relation-name according to the schema.

The above approach was extended in other models by including nodes for explicit representation of tuples and sets (PaMaL, GDM) and n-ary relations (GOAL, GDM). These types of nodes allows the definition of complex structures. Tuple and set nodes of PaMaL are unlabeled, allowing to define (instantiate) more than one entity class (respectively concrete entity) using the same tuple and set node, providing data reduction. Association nodes of GOAL provide simple definition of multi-attribute and multi-valued n-ary relations. Composite-value entities in GDM are used for representing both tuples and n-ary relations.

The basic structure of a graph (nodes and edges) is complemented with the use of hypernodes (Hypernode model, Simatic-XT and GGL) and hypergraphs (GROOVY), extensions that provide support for nested structures. A novel feature of GROOVY is the use of hypergraphs for defining value functional dependencies. The hypernode model is characterized by using nested graphs at the schema and instance level. A database consists of a set of hypernodes defining types and their respective instances. GGL introduces, in addition to its support for hypernodes (called Master-nodes), the notion of *Master-edge* for encapsulation of paths.

Although hypernodes are used in several models, there is a difference in its use. Simatic-XT and GGL use hypernodes as an abstraction mechanism consisting in packaging other graphs as an encapsulated vertex whereas the Hypernode model additionally uses hypernodes to represent other abstractions e.g. complex objects, relations, etc.

A common characteristic between models based on simple and those based on extended graph structures is the support for defining nontraditional data types, feature procured by the definition of complex objects. In this sense, LDM, PaMaL, GOAL and GDM allow the representation of complex objects by defining special constructs (tuple, set or association nodes). Hypernodes and Hypergraphs are flexible data structures that support the representation of arbitrarily complex objects and present inherent ability to encapsulate information.

**3.2.2 Representation of Relations.** Roughly speaking, we can distinguish two types of relations occurring in graph db-models: Simple relations, which connect two entities under a simple semantics (e.g. attributes), and are easily represented

in graphs as edge labels; and complex relations, which conforms networks of relations (e.g. hierarchical) with additional semantics (e.g. composition), and whose representation depends of the data structures provided by each model.

In what follows, we will discuss specific types of relations supported by graph db-models.

—*Attributes.* The relation represents a property (mono-valued or multi-valued) directly linked to an entity. Most graph db-models represent attributes by using labeled edges directly related to nodes.

LDM and PaMaL define tuple nodes to describe a set of attributes that are (re)used to define an entity. In the case of the Hypernode model and GROOVY, attributes are triples  $\langle node, edge, node \rangle$  inside hypernodes or hyperedges which represent complex objects. The (unlabeled) edge establishes the relation between the attribute-name (first node) and the attribute-value (second node). GOOD and GOAL define edges (called functional and non-functional) to distinguish between mono-valued and multi-valued attributes.

—*Entities.* If the relation of two or more objects conceptually describes a distinct model object, such relation is considered an entity. This approach implies support for higher-order relations (relations between relations). Most models do not support this feature because relations are represented as simple labeled edges.

A partial support is presented in GOAL, where association nodes may have properties. The Hypernode model and GROOVY have inherent support because property-names can be complex objects represented as hypernodes or hyperedges. GGL supports this feature by labeling edges with types.

—*Neighborhood relations.* Models with a basic graph structure provide simple support and visualization of neighborhood relations, although special structures used by some of these models (e.g. tuple-nodes in PaMaL) can obscure the simplicity of representation.

In the case of hypergraph and hypernode base models, neighborhood relations are translated into nested relation. A particular modeling structure is the Master-edge of Simatic-XT, which is used for representing *Path relations*.

—*Standard abstractions.* The most frequently used are aggregation (is-part-of relation) and its opposite composition (is-composed-by relation), association (n-ary relations) and grouping or sets.

Some models provide explicit representation of tuples (LDM, PaMaL, GDM), sets (LDM, PaMaL) and n-ary relations (GOAL, GDM). Models based on hypernodes and hypergraphs support grouping by joining entities within an hypernode or an hyperedge.

—*Derivation and inheritance.* These abstraction are represented at the schema level by relations of subclass and superclass (ISA) and at the instance level by relations of instantiation (is-of-type). The notion of inheritance (only structural-attribute inheritance) is supported using these relations, allowing entity classes with overlapping structure to share their semantic content.

ISA relations are explicitly supported in PaMaL, GOAL, and GDM by considering ISA-labeled edges as class-hierarchy links. However note that this type of relation can be implicitly considered as an attribute relation. The Hypernode

and GROOVY models show how structural inheritance is supported naturally by nested-graph structures. The representation of object-class schemas by means of hypergraphs leads to a natural formalization of the notion of object sharing and structural inheritance.

—*Nested relations*. Recursively specified relations defined by nested objects.

This feature is naturally supported by using hypernode or hypergraph structures.

### 3.3 Integrity Constraints

Integrity constraints are general statements and rules, which define the set of consistent database states or changes of state or both [Codd 1980]. Integrity constraints have been studied for the relational [Date 1981; Thalheim 1991], semantic [Weddell 1992; Thalheim 1996], object oriented [Schewe et al. 1993], and semistructured [Buneman et al. 1998; Alechina et al. 2003] db-models. Thalheim [1996] presents a unifying framework for integrity constraints.

In the case of graph db-models, examples of integrity constraints include schema-instance consistency, identity and referential integrity constraints, functional and inclusion dependencies. Next we study each of them.

**3.3.1 Schema-instance consistency.** Entity types and type checking constitute a powerful data-modeling and integrity checking tool, since they allow database schemas to be represented and enforced. Some graph db-models do not define a schema (e.g. first version of Hypernode, Simatic-XT, and initial versions of GGL),

The approach applied in most models (GOOD, GMOD, PaMaL, GOAL, G-log, GDM and Gram) to confront the issue of schema-instance consistency follow in general two guidelines: (i) the instance should contain only concrete entities and relations from entity types and relations that were defined in the schema; (ii) an entity in the instance may only have those relations or properties defined for its entity type (or for a super-type in the case of inheritance). Then, all node and edge labels occurring in the instance must occur in the scheme too, but the opposite is not required in some models (GOOD, GMOD, GOAL and G-Log). In this way, incomplete or non-existing information can be incorporated in the database. PaMaL, GDM and Gram do not support incomplete information because they establish an instantiation function between schema and instance.

LDM define a logic (similar to relational tuple calculus) used to specify integrity constraints on LDM schemas and to define views. Integrity constraints are LDM formulas which enforce that instance objects should satisfy certain conditions (satisfaction of LDM formulas). That is, given a database and a sentence in the logic, one can test effectively whether the sentence is true in the database or not.

GROOVY introduce the notion of object-class schemas over which objects are defined. An object schema defines valid objects (value-schemas), value functional dependencies, and valid shared values between objects (sub-object schemas). These restrictions are formalized using a hypergraph representation. Indeed, there is a one-to-one correspondence between each object schema and a hypergraph, where objects are vertices, value functional dependencies are directed hyperedges, and sub-object schemas are undirected hyperedges.

Additionally, conflicts of inheritance are discussed in some models. The general approach is the notion of consistent schema to prevent problems. GOAL establishes

that objects only belong to the class they are labeled with and their super-classes. This implies that an object can only belong to two classes at once if these classes have a common subclass. PaMaL does not provide a conflict resolution mechanism, since the authors consider that this has to be part of the implementation.

Checking consistency is also related to restructuring, queries and updates of the database (e.g. deletion of entity types or relations in the schema implies the deletion of concrete entities in the instance). Given an arbitrary GOOD program, i.e. a sequence of GOOD operations, statically checking the consistency of an edge addition in the program is undecidable in general. In GMOD the notion of schema-instance consistency is referenced to consistency of schema transformations in object-oriented databases [Zicari 1991]. In PaMaL an addition or deletion operation specifies a valid graph transformation between two instance graphs (schema transformations are not included).

In [Poulovassilis and Levene 1994] the authors show that testing a hypernode repository for well typedness can be performed in polynomial time with respect to the size of the repository. GDM presents a systematic study of the complexity of well-typedness checking: deciding well-typedness of a pattern with no ISA edges under a schema graph with no implicit object class nodes is in PTIME; deciding well-typedness of a pattern under a schema graph with no implied object class nodes is co-NP complete; deciding well-typedness of an addition/deletion under a schema graph with no implied object class nodes is in PSPACE; deciding well-typedness of an addition under a schema graph with no implied object class nodes and no composite-value classes is in PTIME.

*Schema-instance separation.* Another aspect to consider is the degree to which schema and instance are different objects in the database (an issue discussed largely in semistructured db-models). Representation of (un)structured entities means that the data (does not) respect a previously defined data type. In this sense, a data model can be classified as structured or non-structured in terms that it allows or not the definition of a schema that restrict the database instance to well-typed data.

In most models there is a separation between the database schema and the database instance. An exception is the hypernode model presented in [Levene and Loizou 1995], where the lack of typing constraints on hypernodes has the advantage that changes to the database can be dynamic.

*Redundancy of data.* Because an instance graph can contain many instances of entities, e.g. non-printable nodes (GOOD), set/tuple nodes (PaMaL), association nodes (GOAL) or composite-value nodes (GDM), the database presents redundant information. One possible solution is to introduce an operation which is used to group entities on the basis of some of their relations. This abstraction creates a unique entity for each equivalence class of duplicate entities; as such, it acts as a duplicate eliminator. The correspondent operations are Abstraction (GOOD), Reduce (PaMaL) and Reduction (GDM). This operation is informally mentioned in GOAL as a merge of nodes representing the same value.

**3.3.2 Object identity and referential integrity.** Set-based data models such as the relational model and the nested relational model are value-based, that is, tuples in relations (respectively nested relations) are identified by the values of their

attributes. On the other hand, in O-O db-models object identity is independent of attribute values and is achieved by equipping each database object with a unique identifier (e.g. a label). Graph db-models implement the two types of identification, but several advantages accrue with identifiers: (i) arbitrarily complex objects can be identified and referred, (ii) objects can share common sub-objects thus making possible the construction of general networks, and (iii) query and update operation can be simplified.

In some models, concrete entities like instance nodes (PaMaL, Gram), edges (GGL), hypernodes (Hypernode based models), hyperedges (GROOVY) are labeled with entity identifiers, whereas in models like GOOD, GMOD, GOAL, G-Log and GDM each entity is identified by its attributes, although it exists independently of their properties (it is considered as object identity).

The Hypernode Model [Poulovassilis and Levene 1994] defines two integrity constraints: *Entity Integrity* enforces that each hypernode is a unique real world entity identified by their content; *Referential Integrity* requires that only existing entities be referenced. Similarly, GGL [Graves et al. 1995a] establish that (i) labels in a graph are uniquely named; (ii) edges are composed of the labels and vertices of the graph in which the edge occurs. These constraints are similar to primary key and foreign key (referential) integrity constraints in the relational db-model.

**3.3.3 Functional dependencies.** In the Hypernode model [Levene and Loizou 1995] the notion of semantic constraints were considered. The concept of *Hypernode functional dependency*, denoted by  $A \rightarrow B$ , where  $A$  and  $B$  are sets of attributes, let us express that  $A$  determines the value of  $B$  in all hypernodes of the database.

GROOVY [Levene and Poulovassilis 1991] uses *directed hyperedges* to represent *Value Functional Dependencies (VFDs)*, which are used in the value schema level to establish semantic integrity constraints. A VFD asserts that the object value restricted to a set of attributes uniquely determines the object value restricted to a further attribute.

Finally, let us remark that the notion of integrity constraint in graph db-models is concentrated in the creation of consistent instances and the correct identification and reference of entities. The notion of functional dependency is a feature taken from the relational model that cannot be presented easily in all graph db-model.

### 3.4 Query and Manipulation Language

A query language is a collection of operators or inferencing rules which can be applied to any valid instances of the data structure types of the model, with the objective of manipulating and querying data in those structures in any combinations desired [Codd 1980]. A great deal of papers discuss the problems concerning the definition of a query language for a db-model [Vardi 1982; Hull and King 1987; Ramakrishnan and Ullman 1993; Heuer and Scholl 1991; Abiteboul 1997; Abiteboul and Vianu 1997]. Also a variety of query languages and formal frameworks for studying them have been proposed and developed, including the relational db-model [Chandra 1988], semantic databases [Azmoodeh and Du 1988; Andries and Engels 1993], object-oriented databases [Kifer et al. 1992], semistructured data [Buneman et al. 1996; Abiteboul 1997; Abiteboul et al. 1997] and the Web [Abiteboul and Vianu 1997; Florescu et al. 1998].

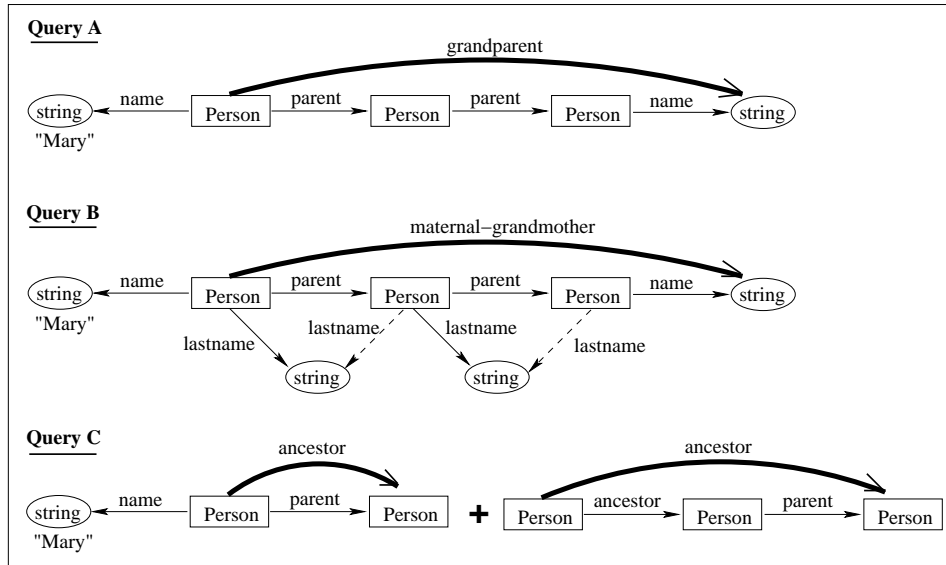

Fig. 3. Example of a graphical query language. The figure shows a G-Log query for the instance in Figure 12. *Query A* asks for the names of Mary's grandparents (fixed path query). *Query B* asks for the name of the maternal grandmother of Mary (tree-like query). *Query C* calculates Mary's Ancestors (transitive closure).

Among graph db-models, there is substantial work focused in query languages, the problem of querying graphs, the visual presentation of results, and graphical query languages. Due to the volume of the research done, this specific area deserves by itself a thorough survey. Considering the scope of this survey, in this section we limit ourselves to describe the most important query languages to serve as reference resource.

The Logical Database Model [Kuper and Vardi 1984; 1993] presents a logic language very much in the spirit of relational tuple calculus, which uses fixed sort variables and atomic formulas to represent queries over a schema using the power of full first order languages. The result of a query consists of those objects over a valid instance that satisfy the query formula. In addition the model presents an alternative algebraic query language proven to be equivalent to the logical one.

The proposal G-Log [Paredaens et al. 1995] includes a declarative language for complex objects with identity. It uses the logical notion of *rule satisfaction* to evaluate queries which are expressed as G-Log programs. *G-Log programs* are sets of graph-based rules, which specify how the schema an instance of the database will change. G-Log is a graph-based, declarative, nondeterministic, and computationally complete query language that does not suffer from the copy-elimination problem. G-Log is a good example of graphical query language, see Figure 3.

Oriented to search the Web, Flesca and Greco [1999] show how to use partially ordered languages to define path queries to search databases and present results on their computational complexity. In addition, a query language based on the previous ideas is proposed in [Flesca and Greco 2000].

Cardelli et al. [2002] introduced a spatial logic for reasoning about graphs and defined a query language based in pattern matching and recursion. This Graph Logic combines first-order logic with additional structural connectives. A query ask for a substitution of variables such that a *satisfaction relation* determines which graph satisfy which formulae. The query language is based on *queries* that build new graphs from old and *transducers* that relate input graphs with output graphs.

In the context of graph-oriented object models, there are query languages that regard database transformations as *graph transformations* (which can be interpreted as database queries and updates). They are based on *graph-pattern matching* and allow the user to specify node insertions and deletions in a graphical way. GOOD [Gyssens et al. 1990] presented a graph-based language that is shown to be able to express all constructive database transformations. This language was followed by the proposals GMOD [Andries et al. 1992], PaMaL [Gemis and Paredaens 1993], GOAL [Hidders and Paredaens 1993], and GUL [Hidders 2002].

Additionally, GOAL includes the notion of *fixpoints* in order to handle the recursion derived from a finite list of additions and deletions. PaMaL proposed the inclusion of *Loop, Procedure and Programs constructs*, and PaMaL and GUL presented an operator that reduces instance graphs by deleting repeated data. Note that graph-oriented manipulation formalisms based on patterns allow a syntax-directed way of working much more natural than text-based interfaces.

The query languages G, G+ y GraphLog integrate a family of related graphical languages defined over a general simple graph model.

- The graphical query language G [Cruz et al. 1987] is based on regular expressions that allow simple formulation of recursive queries. A *graphical query* in G is a set of labeled directed multigraphs where nodes may be either variables or constants, and edges can be labeled with regular expressions. The result of a query is the union of all query graphs which match subgraphs from the instance.
- G evolved into a more powerful language called G+ [Cruz et al. 1989] where a query graph remains as the basic building block. A simple query in G+ has two elements, a query graph that specifies the class of patterns to search and a summary graph that represent how to restructure the answer obtained by the query graph.
- GraphLog [Consens and Mendelzon 1989] is a query language for hypertext that extends G+ by adding negation and unifying the concept of a query graph. A query is now only one graph pattern containing one distinguished edge, which corresponds to the restructured edge of the summary graph in G+. The effect of the query is to find all instances of the pattern that occur in the database graph and for each one of them define a virtual link represented by the distinguished edge. GraphLog includes an implicit transitive closure operator, which replaces the usual recursion mechanism. The algorithms used in the GraphLog implementation are discussed in [Mendelzon and Wood 1989].

Glide [Giugno and Shasha 2002] is a graph query language where queries are expressed using a linear notation formed by labels and wild-cards (regular expressions). Glide uses a method called GraphGrep based on subgraph matching to answer the queries.

GROOVY [Levene and Poulouvasilis 1991] introduces a Hypergraph Manipulation Language (HML) for querying and updating labeled hypergraphs. It defines two basic operators for querying hypergraphs by identifier or by value, and eight operators for manipulation (addition and deletion) of hypergraphs and hyperedges.

Watters and Shepherd [1990] presents a framework for general data access based in hypergraphs that include operators for creation of edges and set operators like intersection, union and difference. In a different context, Tompa [1989] introduces basic operations over hypergraph structures representing user state and views in page-oriented hypertext data.

The literature also include proposals of query languages that deal with *hypernode* structures:

- The Hypernode model [Levene and Poulouvasilis 1990] defines a logic-based query and update language, which is based in the expression of queries as sets of hypernode rules (h-rules) that are called *hypernode programs*. The query language defines an operator which infers new hypernodes from the instance using the set of rules in a hypernode program.
- This query language was extended by Hyperlog [Poulouvasilis and Levene 1994; Poulouvasilis and Hild 2001] including deletions as well as insertions, and discussing in more detail the implementation issues. A full Turing-machine capability is obtained by adding composition, conditional constructs and iteration. Hyperlog is computationally and update complete. Although the evaluation of Hyperlog programs is intractable in the general case.
- In a procedural style, HNQL [Levene and Loizou 1995] defines a set of operators for declarative querying and updating of hypernodes. It also includes assignment, sequential composition, conditional (for making inferences), for loop, and while loop constructs.

In the area of Geographic information Systems, the Simatic-XT model [Langou and Mainguenaud 1994] defines a query language. It includes basic operators that deal with encapsulated data (nesting of hypernodes), set operators (union, concatenation, selection and difference) and high level operators (paths, inclusion and intersections).

WEB [Graves 1993; Graves et al. 1994] is a declarative programming language based on a graph logic and oriented to querying genome data. WEB programs define graph templates for creating, manipulating and querying objects and relations in the database. These operations are answered by matching graphs in valid instances.

Models like Gram [Amann and Scholl 1992] and GOQL [Sheng et al. 1999] propose SQL-Style query languages with explicit path expressions. *Gram* presents a query algebra where regular expressions over data types are used to select walks (paths) in a graph. It uses a data model where walks are the basic objects. A walk expression is a regular expression without union, whose language contains only alternating sequences of node and edge types, starting and ending with a node type. The query language is based on a hyperwalk algebra with operations closed under the set of hyperwalks.

Models like DGV [Gutiérrez et al. 1994] and GraphDB [Gütting 1994] define special operators for functional definition and querying of graphs. For example,

a query in GraphDB consists of several steps, each of one computes operations that specify argument subgraphs in the form of regular expressions over edges that extend or restrict dynamically the database graph. GraphDB includes a class of objects called path class, which are used to represent several paths in the database.

One of the most fundamental graph problems in graph query languages is to compute reachability of information, which translates into path problems characterized and expressed by recursive queries. For example, path queries are relevant in GraphLog, Gram, Simatic-XT, DGV, GOQL, Flesca and Grego, Cardelli et al., and in less degree treated in Hypernode, GOAL, Hyperlog, GraphDB, G-Log, and HNQL. The notion of shortest path is considered in Flesca and Greco, G+, GraphLog, and DGV. Path and other relevant graph queries for RDF are discussed in [Angles and Gutierrez 2005].

The importance and computational complexity of path-based queries is studied in several works [Agrawal and Jagadish 1994; 1989; 1988; R.V.Guha et al. 1998]. Finding simple paths with desired properties in direct graphs is difficult, and essentially every nontrivial property gives rise to an NP-complete problem [Shasha et al. 2002]. Yannakakis [1990] surveyed a set of paths problems relevant to the database area including computing transitive closures, recursive queries and the complexity of path searching. Mannino and Shapiro [1990] present a survey of extensions to database query languages for solve graph traversal problems.

## A. REPRESENTATIVE GRAPH DATABASE MODELS

In this section we describe the most representative graph db-models mentioned in Table 4 and other related models that do not fit properly as graph db-models, but use graphs, for example, for navigation, for defining views, or as language representation.

For each proposal, we present their data structures, query language and integrity constraint rules. In general, there are few implementations and no standard benchmarks, hence we avoid surveying implementations (for information about the existence of implementations see Figure 4). To give a flavor of the modeling in each proposal, we will use as running example the toy genealogy shown in Figure 5.

### A.1 Logical Data Model (LDM)

Motivated by the lack of semantics in the relational db-model, Kuper and Vardi [1984] proposed a db-model that generalizes the relational, hierarchical and network models. The model describes mechanisms to restructure data plus a logical and an algebraic query languages.

In LDM a *schema* is an arbitrary directed graph where each node has one of the following types: the *Basic* type  $\square$  describes a node that contains the data stored; the *Composition* type  $\sqcap$  describes a node that contains tuples whose components are taken from its children; the *Collection* type  $\circ$  describes a node that contains sets, whose elements are taken from its child. Hence, internal nodes are of type  $\otimes$  or  $\circledast$  representing structured data, terminal nodes are of type  $\square$  and represent atomic data, and edges represent connections between data.

A second version of the model [Kuper and Vardi 1993], besides renaming the nodes Composition and Collection as *Product*  $\otimes$  and *Power*  $\circledast$  respectively, incorporates a new type, the *Union* type  $\cup$ , intended to represent a collection whose domain is the union of the domains of its children (see example in Figure 6).

An LDM database *instance* consists of an assignment of values to each node of the schema. The instance of a node is a set of elements from the underlying domain (for basic type nodes) and tuples or sets taken from the instance of the node's children (for  $\otimes$ ,  $\circledast$  and  $\cup$  types).

With the objective of avoiding cyclicity at the instance level, the model proposes to keep a distinction between memory locations and their content. Thus, instances consist of a set of *l-values* (the address space), plus an *r-value* (the data space)

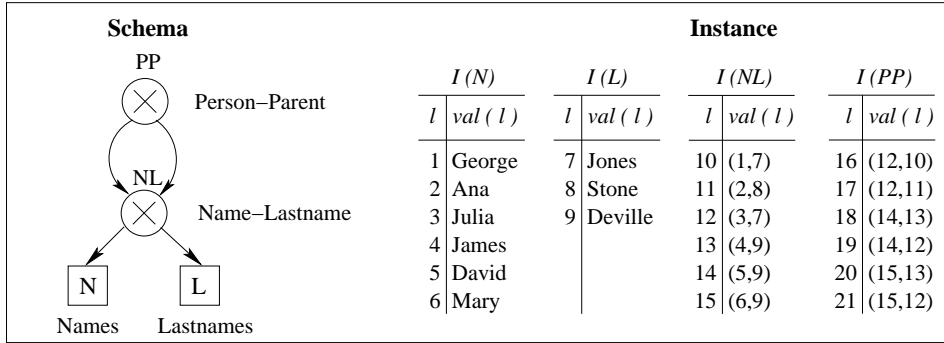

Fig. 6. Logical Data Model. The schema (on the left) uses two basic type nodes for representing data values (N and L), and two product type nodes (NL and PP) to establish relations between data values in a relational style. The instance (on the right) is a collection of tables, one for each node of the schema. Note that internal nodes use pointers (names) to make reference to basic and set data data values defined by other nodes.

assigned to each of them. These features allow to model transitive relations like hierarchies and genealogies.

Over this structure a first order many-sorted language is defined. With this language, a query language and integrity constraints are defined. Finally, an algebraic language –equivalent to the logical language– is proposed, providing operations for node and relation creation, transformation and reduction of instances, and other operations like union, difference and projection.

LDM is a complete db-model (*i.e.* data structures plus query languages and integrity constraints) that supports modeling of complex relations (*e.g.* hierarchies, recursive relations). The notion of virtual records (pointers to physical records) proves useful to avoid redundancy of data by allowing cyclicity at the schema and instance level. Due to the fact that the model is a generalization of other models (like the relational model), their techniques or properties can be translated into the generalized model. A relevant example is the definition of integrity constraints.

### A.2 Hypernode Model

The Hypernode db-model was described in a sequence of papers [Levene and Poulouvasilis 1990; Poulouvasilis and Levene 1994; Levene and Loizou 1995]. A hypernode is a directed graph whose nodes can themselves be graphs (or hypernodes), allowing nesting of graphs. Hypernodes can be used to represent *simple* (flat) and *complex objects* (hierarchical, composite, and cyclic) as well as mappings and records. A key feature is its inherent ability to *encapsulate information*.

The hypernode model was introduced by Levene and Poulouvasilis [1990], who define the model and a declarative logic-based language structured as a sequence of instructions (hypernode programs), used for querying and updating hypernodes. The implementation of a storage system based on the hypernode model is presented in [Tuv et al. 1992].

In a second version [Poulouvasilis and Levene 1994], the notion of schema and type checking is introduced via the idea of types (primitive and complex), that

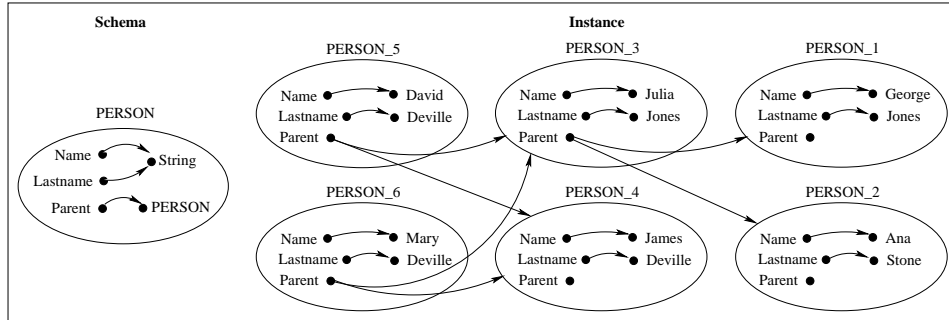

Fig. 7. Hypernode Model. The schema (left) defines a *person* as a complex object with the properties *name* and *lastname* of type string, and *parent* of type person (recursively defined). The instance (on the right) shows the relations in the genealogy among different instances of person.

are also represented by nested graphs (See an example in Figure 7). The model is completed with entity and referential integrity constraints over an hypernode repository. Moreover it presents a rule-based query language called *Hyperlog*, which can support both querying and browsing with derivations as well as database updates, and is intractable in the general case.

A third version of the model [Levene and Loizou 1995] discusses a set of constraints (entity, referential and semantic) over hypernode databases and introduces the concept of *Hypernode functional dependency (HDF)*, denoted by  $A \rightarrow B$ , where  $A$  and  $B$  are sets of attributes, and  $A$  determines the value of  $B$  in all hypernodes of the database. In addition it presents another query and update language called HNQL, which use compounded statements to produce HNQL programs.

Summarizing, the main features of the Hypernode model are: it is based on a nested graph structure which is simple and formal; it has the ability to model arbitrary complex objects in a straightforward manner; it can provide the underlying data structure of an object-oriented data model; it can enhance the usability of a complex objects database system via a graph-based user interface.

As drawbacks, we can mention that data redundancy can be generated by its basic value labels, and that restrictions in the schema level are limited, for example the specification of restrictions for missing information or multivalued relations is not possible.

### A.3 Hypergraph-Based Data Model (GROOVY)

GROOVY (Graphically Represented Object-Oriented data model with Values [Levene and Poulouvasilis 1991]) is a proposal of object-oriented db-model which is formalized using *hypergraphs*, that is, a generalization of graphs where the notion of edge is extended to *hyperedge*, which relates an arbitrary set of nodes [Berge 1973]. An example of hypergraph schema and instance is presented in Figure 8.

The model defines a set of structures for an object data model: value schemas, objects over value shemas, value functional dependencies, object schemas, objects over objects schemas and class schemas. The model shows that these structures can be defined in terms of hypergraphs.

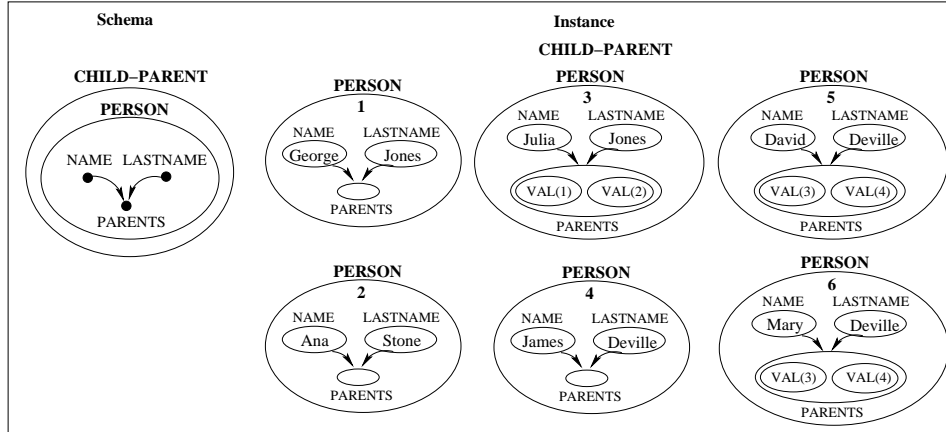

Fig. 8. GROOVY. At the schema level (left), we model an object *PERSON* as an hypergraph that relates the attributes *NAME*, *LASTNAME* and *PARENTS*. Note the value functional dependency (VDF)  $NAME, LASTNAME \rightarrow PARENTS$  logically represented by the directed hyperedge  $(\{NAME, LASTNAME\} \{PARENTS\})$ . This VFD asserts that *NAME* and *LASTNAME* uniquely determine the set of *PARENTS*.

A *Value Schema* defines the attributes (atomic or multi-valued) that contain a class of object. Attributes in value schemas can be themselves value schemas, allowing representation of complex objects and encapsulation of information. An *Object over a value schema* is a pair  $O = \langle i, v \rangle$  where  $i$  is the object-ID (identity) and  $v$  is the object value (properties). A *Value Functional Dependency* is used at the value schema level to assert that the value of a set of attributes uniquely determines the value of other attribute. The determined attribute can be single-valued or multi-valued. An *Object Schema* is a triple  $\langle N, F, S \rangle$ , where  $N$  is a value schema,  $F$  is a set of value functional dependencies over  $N$ , and  $S$  is a set of subsets of  $N$  including  $N$  itself.  $S$  represents sub-object schemas which describe the potential sharing between objects and subjects. A *Class Schema* is a triple  $\langle N, F, H \rangle$  such that  $H \subseteq \mathcal{P}(N)$  and  $N \in H$ .  $H$  defines a super-class schema/sub-class schema relationship which induces a partial ordering of class schemas, the inheritance lattice.

There is a one-to-one correspondence between each object schema  $\langle N, F, S \rangle$  and a hypergraph, interpreting  $N$  as vertices,  $F$  as directed hyperedges, and  $S$  as undirected hyperedges. The same approach is applied for representing class schemas and objects in the instance level.

A hypergraph manipulation language (HML) for querying and updating hypergraphs is presented. It has two operators for querying hypergraphs by identifier or by value, and eight operators for manipulation (insertion and deletion) of hypergraphs and hyperedges.

The use of hypergraphs has several advantages. It introduces a single formalism for both sub-object sharing and structural inheritance, avoiding redundancy of data (values of common sub-objects are shared by their super-objects). Hypergraphs allow the definition of complex objects (using undirected hyperedges), functional dependencies (using directed hyperedges), object-ID and (multiple) structural in-

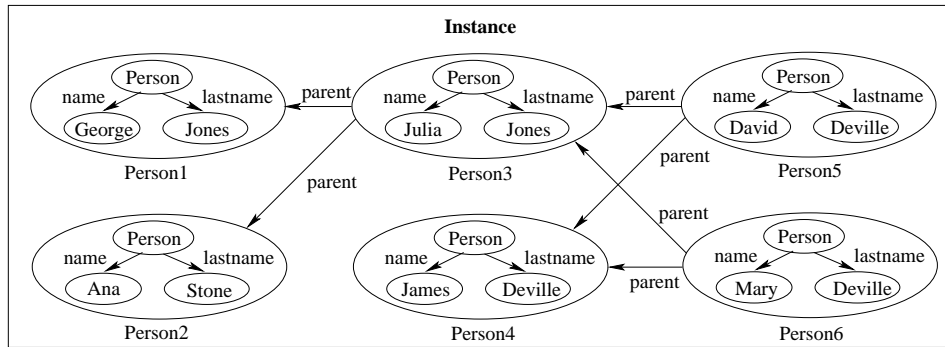

Fig. 10. GGL. Schema and instances are mixed. *Packaged graph vertices* (*Person1*, *Person2*, ...) are used to encapsulate information about the graph defining a *Person*. Relations between these packages are established using edges labeled with *parent*.

The model can be represented as a labeled directed multi-graph, defining three basic types: *Node type*, *Edge type*, and *Network type* (representing a graph). Additionally, the model introduces the notion of *Master Nodes* and *Master Edges*, to support levels of abstraction of sub-networks and paths respectively. Each object in the model has an object identifier (OID), that permits identification and referencing. The level of abstraction is given by the nested level of Master Nodes and Edges Nodes. The model defines the attribute *in\_edges* to represent the set of edges arriving in the subgraph (resp. path) that the Master Node (resp. Master Edge) represents. In the same form *out\_edges* represent the set of edges leaving the Master node or Master Edge.

A sequel paper [Langou and Mainguenaud 1994] presents a set of graph operators divided into three classes: *Basic operators*, managing the notion of abstraction (the Develop and Undevelop operators); *Elementary operators*, managing the notion of graph and sub-graph (Union, Concatenation, Selection and, Difference) and; *high level operators* (Paths, Inclusions and Intersections).

This proposal allows simple modeling and abstraction of complex objects and paths, and encapsulation at node and edge levels. It improves the representation and querying of paths between nodes, and the visualization of complex nodes and paths. At its current state, it lacks definition of integrity constraints.

### A.5 Graph Database System for Genomics (GGL)

This db-model comes from the biology community and highlights the advantage of storing Genome maps as graphs. GGL includes a graph-theoretic db-model [Graves et al. 1995a], a genome graph language [Graves et al. 1995b], and query operators for the model [Graves et al. 1994; Graves 1993].

The model is based on binary relationships between objects. This model extends the basic notion of a graph by including vertices that represent edge types which allow to specify relations between relations (higher-order relations), and encapsulated graphs as vertices. An example is presented in Figure 10.

A graph in GGL is basically a collection of: *Simple vertices* which model simple concepts and can be labeled or unlabeled; *Symbols* that define nodes without

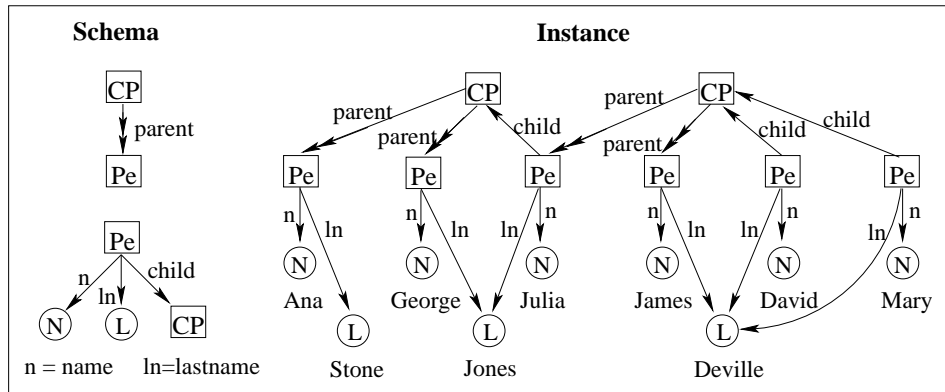

Fig. 11. GOOD. In the schema, we use printable nodes  $N$  and  $L$  to represent names and lastnames respectively and non-printable nodes  $Pe$ (rson) and  $CP$  to represent relations Name-Lastname and Child-Parent respectively. A double arrow indicates non-functional relationship, and a simple arrow indicates functional relationship. The instance is got by assigning values to printable nodes and instantiating the  $CP$  and  $PE$  nodes.

outgoing edges; *Edges* that connect two vertices and are labeled with a relation name; *Packaged graph vertices* that represent graphs which are packaged (encapsulated) into vertices; and *Relation type vertices* which are used to represent relations between relations (higher-order relations). According to this definition, the graph data structure consists of a directed labeled, possibly cyclic, which maintains hierarchically-ordered graphs.

For querying data in this model, two methods are proposed: The first [Graves et al. 1994] restrict the form of the query graph to be rooted directed acyclic graphs with equality constraints. The strategy is based in following the paths specified by the query-graph and returning the values that correspond to the end of the paths. The second, is a declarative programming language called WEB [Graves 1993], that defines queries as graphs with the same structures of the model and return the graphs in the database which *match* the query-graph.

Finally, the model defines two database-independent integrity constraints: Labels in a graph are uniquely named, and edges are composed of the labels and vertices of the graph in which the edge occurs.

The model was designed to support the requirements to model genome data, but also is generic enough to support complex interconnected structures. The distinction between schema and instance is blurred. Its nesting levels increase the complexity of modeling and processing.

#### A.6 Graph Object Oriented Data Model (GOOD)

The Graph Object Oriented Data Model [Gyssens et al. 1990] is a proposal oriented mainly to develop database end-user graphical interfaces [Gyssens et al. 1990]. In GOOD, schema and instances are represented by directed labeled graphs, and the data manipulation is expressed by graph transformations. An example of its application is the database management system presented in [Gemis et al. 1993]. The GOOD schema and instance for the general example is presented in Figure 11.

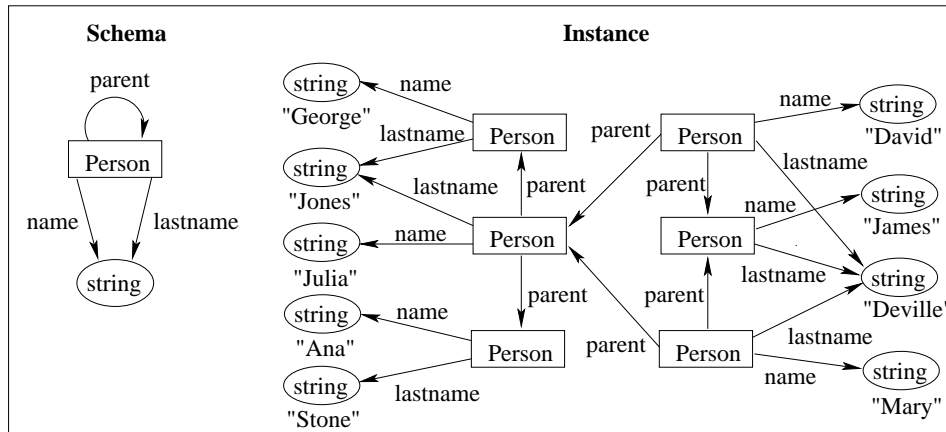

Fig. 12. GMOD. In the schema, nodes represent abstract objects (*Person*) and labeled edges establish relations with primitive objects (properties *name* and *lastname*) and other abstract objects (*parent* relation). For building an instance, we instantiate the schema for each person by assigning values to oval nodes.

The model permits only two types of nodes, non-printable nodes (denoted by squares) and printable nodes (denoted by circles). There is no distinction between atomic, composed and set objects. There are two types of edges, functional (have a unique value, denoted by  $\rightarrow$ ) and non-functional (multi-valued and denoted by  $\rightarrow\rightarrow$ ). A more detailed version [Gyssens et al. 1991] added node and edges for representing set containment, object composition, generalization, and specialization.

GOOD includes a data transformation language with graphical syntax and semantics. It contains four elementary graph transformation operations: addition and deletion of nodes and edges, plus a fifth operation called abstraction, used to group nodes on the basis of common functional or non-functional properties. The specification of all these operations relies on the notion of pattern to describe subgraphs in the database instance. GOOD study other issues like macros (for more succinct expression of frequent operations), computational-completeness of the query language, and simulation of object-oriented characteristics (i.e. inheritance).

The model presented introduced several useful features. The notion of printable and non-printable nodes is relevant for the design of graphical interfaces. It has a simple definition of multivalued relations and allows recursive relations. It solves in a balanced way the data redundancy problem.

### A.7 Graph-oriented Object Manipulation (GMOD)

GMOD [Andries et al. 1992] is a proposal of a general model for object database concepts focused on graph-oriented database user interfaces. Schema and instance are labeled digraphs. An example is presented in Figure 12.

The *schema* graph has two class of nodes, *abstract objects* (rectangular shape) representing class names and, *primitive objects* (oval shape) representing basic types. Edges represent properties of abstract objects. Distinction between single-value and multi-value properties is not considered.

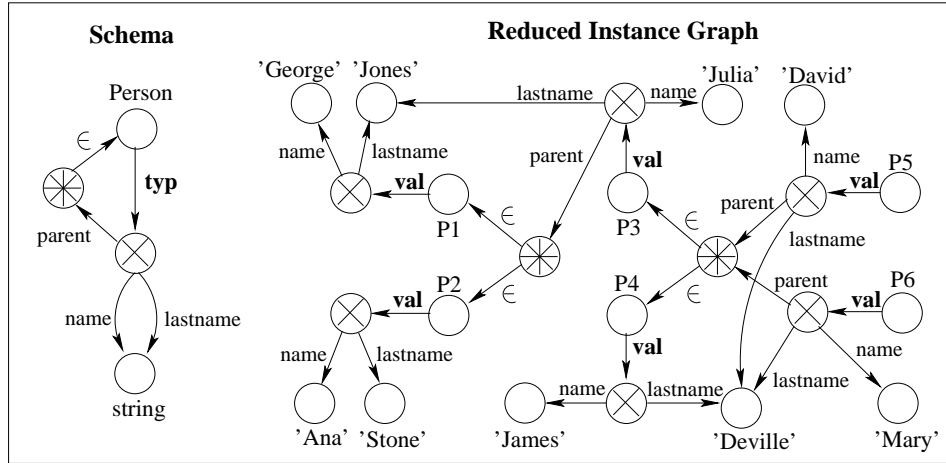

Fig. 13. PaMaL. The example shows all the nodes defined in PaMaL: basic type (*string*), class (*Person*), tuple ( $\otimes$ ), set ( $\oplus$ ) nodes for the schema level, and atomic (*George*, *Ana*, etc.), instance (*P1*, *P2*, etc), tuple and set nodes for the instance level. Note the use of edges  $\in$  to indicate elements in a set, and the edge **typ** to indicate the type of class *Person* (these edges are changed to **val** in the instance level).

The *instance* graph contains the data and includes instance nodes for abstract and primitive objects (represented as in the schema level). The latter have an additional label indicating their value (according to the primitive object domain). The same edges defined in the schema are used to represent the properties of instance objects, but their use is not necessarily required (incomplete information is allowed). Formally, there is a graph morphism from the graph instance (without the labels indicating value) to the schema.

The model uses graph pattern matching as a uniform object manipulation primitive for querying, specification, updating, manipulation, viewing and browsing.

The model allows a simple representation of objects and relations, incomplete information, and permits avoiding redundancy of data. The issue of property-dependent identity and a not completely transparent notion of object-ID incorporates some complexities in the modeling.

G-Log [Paredaens et al. 1995] is a proposal of a declarative query language for graphs, which works on the data structures defined by GMOD. Queries in G-log are expressed by programs which consist of a number of rules and use patterns (denoted as graphs with variables in the nodes and predicates in the edges) to match subgraphs in the instance.

### A.8 Object Oriented Pattern Matching Language (PaMaL)

PaMaL is a graphical data manipulation language that uses patterns (represented as graphs) to specify the parts of the instance on which the operation has to be executed. Gemis and Paredaens [1993] proposed this pattern-based query language based on a graphical object-oriented db-model as an extension of GOOD by an explicit representation of tuples and sets. An example of PaMaL schema and instance is presented in Figure 13.

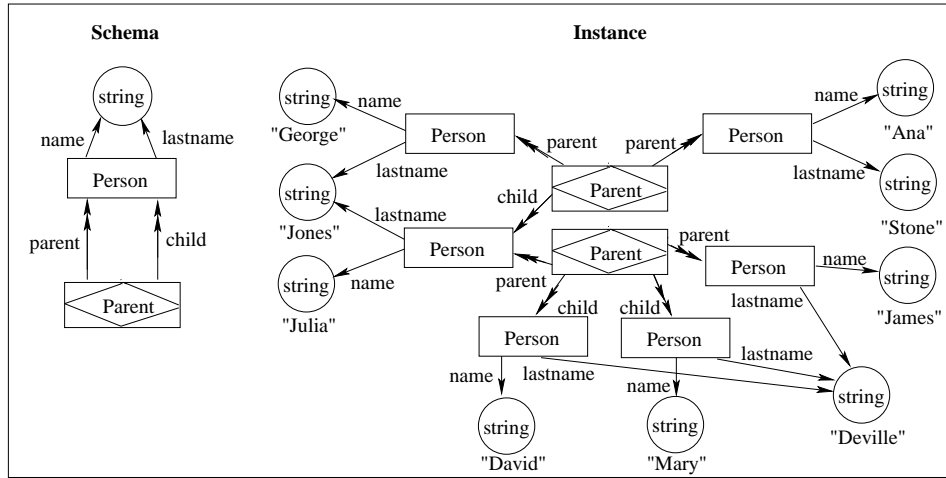

Fig. 14. GOAL: The schema presented in the example shows the use of the object node *Person* with properties Name and Lastname. The association node *Parent* and the double headed edges *parent* and *child* allow to express the relation Person-Parent. At the instance level, we assign values to value nodes (*string*) and create instances for object and association nodes. Note that nodes with same value were merged (e.g. *Deville*).

The *schema* defines four types of Nodes: ○ class nodes (upper-case labels), ○ basic-type nodes (lower-case labels), ⊗ tuple nodes, and ⊛ set nodes. There are four kinds of edges, indicating attribute of a tuple, type of the elements in a set (labeled with  $\in$ ), type of the classes (labeled with **typ**), and hierarchical relationship (labeled with **isa**).

An *instance* graph may contain *atomic*, *instance*, *tuple* and *set* nodes (they are determined by the schema). *Atomic objects* are labeled with values from their domains and *instance objects* are labeled with object-ID's. *tuple* and *set* objects are identified by their outgoing edges, motivating the notion of *reduced instance graph* to merge nodes that represent the same set or tuple. To refer to the node that describes the properties (or content) of an object, an edge labeled **val** is used and represents the edge **typ** in the schema.

PaMaL presents operators for addition, deletion (of nodes and edges) and a special operation that reduces instance graphs. It incorporates loop, procedure and program constructs that makes it a computationally complete language. Among the highlights of the model are the explicit definition of sets and tuples, the multiple inheritance, and the use of graphics to describe queries.

### A.9 Graph-based Object and Association Language (GOAL)

Motivated by the introduction of more complex db-models like object-oriented ones, and directed to offer the user a consistent graphical interface, Hidders and Paredaens [1993] proposed a graph based db-model for describing schemas and instances of object databases. GOAL extends the model of GOOD by adding the concept of *association* nodes (similar to the entity relationship model). The main difference between associations and objects is that the identity of objects is inde-

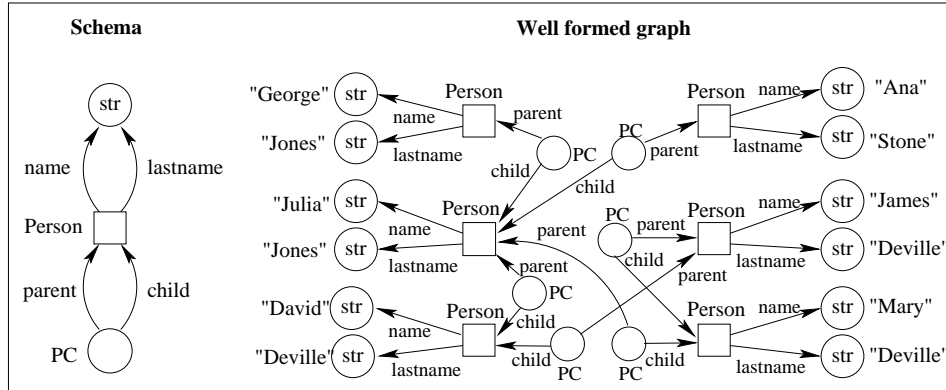

Fig. 15. GDM. In the schema each entity *Person* (object node represented as a square) has assigned the attributes *name* and *lastname* (basic value nodes represented round and labeled *str*). We use the composite-value node *PC* to establish the relationship *Parent-Child*. Note the redundancy introduced by the node *PC*. The instance is built by instantiating the schema for each person.

pendent of their properties, whereas associations are considered identical if they have the same properties. An example is presented in Figure 14.

Schema and instances in GOAL are represented as finite directed labeled graphs. A schema allows to define three types of nodes: *object nodes* that represent objects (rectangular nodes); *value nodes* that represent printable values such as string, integers or booleans (round nodes) and; *association nodes* that represent associations or relations among more than two nodes (diamond shape nodes). Objects and associations may have properties that are represented by edges. The model allows representation of functional properties (single headed edges) and multi-valued properties (double headed edges), as well as ISA relations (double unlabeled arrows). An instance in GOAL assigns values to value nodes and creates instances for object and association nodes.

GOAL introduces the notion of consistent schema to enforce that objects only belong to the class they are labeled with and its super-classes. In addition GOAL presents a graph data manipulation language with operations for addition and deletion based on pattern matching. The addition (deletion) operation adds (deletes) nodes and/or edges at the instance level. A finite sequence of additions and deletions is called a *transformation*.

There are several novelties introduced by this model. Association nodes allow simple definition of multi-attribute and multi-valued relations. In contrast to the Entity Relationship model, GOAL supports relations between associations. Properties are optional, therefore it is possible to model incomplete information. Additionally, GOAL defines restrictions that introduce notions of consistent schema and weak instance.

#### A.10 Graph Data Model (GDM)

GDM [Hidders 2002; 2001] is a graph-based db-model based on GOOD, that adds explicit complex values, inheritance and  $n$ -ary symmetric relationships. Schema and instances in GDM are described by labeled graphs called instance graph and

schema graph respectively. An example is presented in Figure 15.

A *schema* graph contains nodes that represent classes and edges labeled with attribute names indicating that entities in that class may have that attribute. Three types of class nodes are allowed: *object*, *composite-value* and, *basic value*. An edge denoted by a double-line arrow defines an *ISA* relation between class nodes.

In an *instance* graph, nodes represent entities and edges represent attributes of these entities. We can have *object nodes* (depicted squared), *composite-value nodes* (round empty) and *basic value nodes* (round labeled with a basic-type name). An object node is labeled with zero or more class names indicating their membership to certain classes. If several edges with the same label leave a node, then it is a single set-valued attribute.

GDM introduces the concept of well-formed graph defining four constraints: (I-BVA) no edge leaves from a basic-value node; (I-BVT) each basic value node has assigned a real value that is in the domain of the basic-type of the node; (I-NS) for each class-free node  $n$  there is a path that ends in  $n$  and starts in a class-labeled node; and (I-REA) composite-value nodes have either exactly one incoming edge or are labeled with exactly one class name, but not both. In addition the model considers the notion of consistency defining *extension relations* which are many-to-many relations between the nodes in the data graph and nodes in the schema graph, indicating correspondence between entities and classes.

The proposal includes a graph-based update language called GUL, that is based on pattern matching. GUL permits addition and deletion operations, plus a reduction operation that reduces well-formed data graphs to instance graphs by merging similar basic-value nodes and similar composite-value nodes.

The GDM model presents the following benefits. The independence of the definition of the notions of schema and instance permits that instances can exist without a schema, allowing representation of semi-structured data. It permits the explicit representation of complex values, inheritance (using *ISA* edges) and definition of  $n$ -ary symmetric relationships. The composite-value nodes allow simple definition of multi-attribute and multi-valued relations. Finally, let us remark that this model introduces notions of consistency and well-formed graphs.

#### A.11 Gram: A Graph Data Model and Query Language

Motivated by hypertext querying, Amann and Scholl [1992] introduce Gram, a graph db-model where data is organized as a graph. A schema in Gram is a directed labeled multigraph, where each node is labeled with a symbol called a *type*, which has associated a domain of values. In the same way, each edge has assigned a label representing a relation between types (see example in Figure 16). A feature of Gram is the use of regular expressions for explicit definition of paths called *walks*. An alternating sequence of nodes and edges represent an walk, which combined with other walks conforms other special objects called *hyperwalks*.

For querying the model (particularly path-like queries), an algebraic language based on regular expressions is proposed. For this purpose a hyperwalk algebra is defined, which presents unary operations (projection, selection, renaming) and binary operations (join, concatenation, set operations), all closed under the set of hyperwalks.

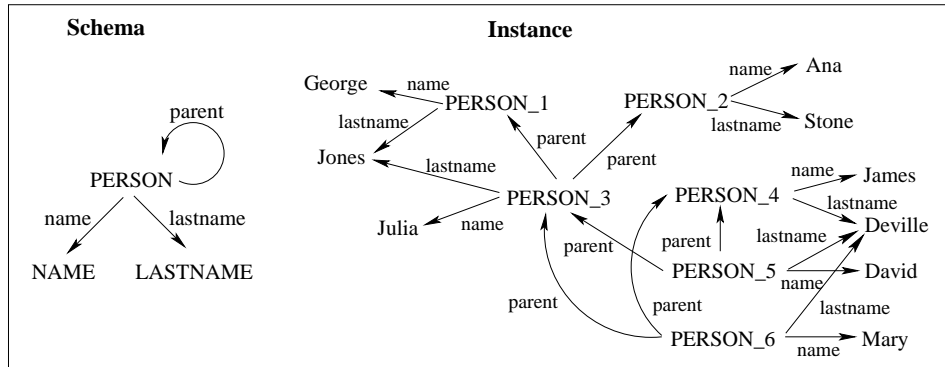

Fig. 16. Gram. At the schema level we use generalized names for definition of entities and relations. At the instance level, we create instance labels (e.g. PERSON\_1) to represent entities, and use the edges (defined in the schema) to express relations between data and entities.

## A.12 Related Data Models

Besides the models reviewed, there are other proposals that present graph-like features, although not explicitly designed to model the structure and connectivity of the information. In this section we will describe the most relevant of these.

**A.12.1 GraphDB.** Güting [1994] proposes an explicit model named GraphDB, which allows simple modeling of graphs in an object oriented environment. The model permits an *explicit representation* of graphs by defining object classes whose objects can be viewed as nodes, edges and explicitly stored paths of a graph (which is the whole database instance). A database in GraphDB is a collection of object classes partitioned into three kinds of classes: simple, link and path classes. Also there are data types, object types and tuple types. There are four types of operators to query GraphDB data: Derive statements, Rewrite operations, Union operator, and Graph operations (Shortest path search).

The idea of modeling graphs using object oriented concepts is presented in other proposals, generically called *object-oriented graph models*. A typical example is GOQL [Sheng et al. 1999], a proposal of graph query language for modeling and querying of multimedia application graphs (represented as DAGs). This proposal defines a object oriented db-model (similar to GraphDB) that defines four types of objects: node, edge, path and graph. GOQL uses an SQL-like syntax for construction, querying and manipulation of such objects.

**A.12.2 Database Graph Views.** A database graph view [Gutiérrez et al. 1994] provides a functional definition of graphs over data that can be stored in either relational, object oriented or file systems. In other words, the model proposes the definition of personalized graph views of the data with management and querying purposes, and independent of its implementation.

In brief the model defines underlying graphs over the database and proposes a set of primitives called *derivation operators* for definition and querying of graph views. Unary derivation operators allow selection of nodes and edges. Binary derivation operators are used to build new graph views resulting from the union, intersection

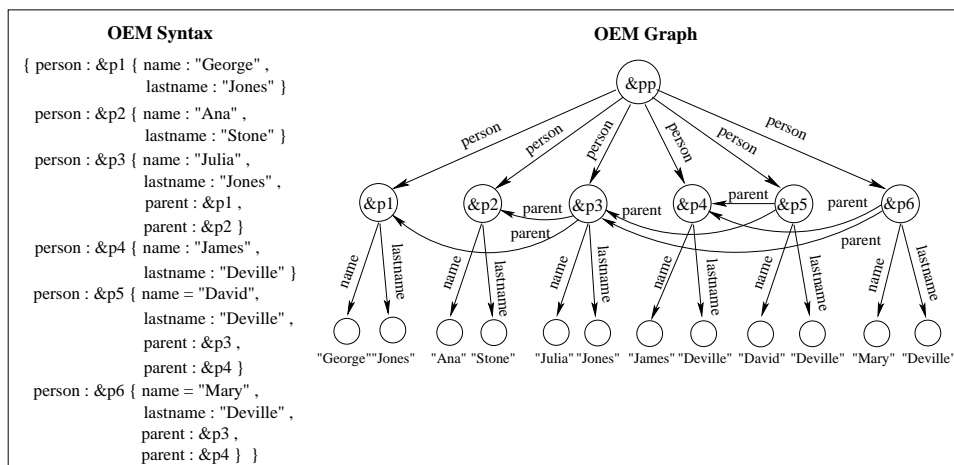

Fig. 17. Object Exchange Model (OEM). Schema and instance are mixed. The data is modeled beginning in a root node  $\&pp$ , with children *person nodes*, each of them identified by an Object-ID (e.g.  $\&p2$ ). These nodes have children that contain data (*name* and *lastname*) or references to other nodes (*parent*). Referencing permits to establish relations between distinct hierarchical levels. Note the tree structure obtained if one forgets the pointers to OIDs, a characteristic of semistructured data.

or difference of two graph views.

**A.12.3 Object Exchange Model (OEM).** OEM [Papakonstantinou et al. 1995] is a semistructured db-model that allows simple and flexible modeling of complex features of a source using the ideas of nesting and object identity from object oriented db-models (features such as classes, methods and inheritance are omitted). The main motivation of OEM was the information integration problem. Therefore it defines a syntax that is well suited for information exchange in heterogeneous dynamic environments. The data in OEM can be represented as a rooted directed connected graph. An example of OEM graph and syntax is presented in Figure 17.

Data represented in OEM can be thought of as a graph with Object-IDs representing node-labels and OEM-labels representing edge-labels. Atomic objects are leaf nodes where the OEM-value is the node value. The main feature of OEM data is that it is self-describing, in the sense that it can be parsed without recurring to an external schema and uses human understandable labels that add semantic information about objects. Due to the fact that there is no notion of schema or object class (although each object defines its own schema), OEM offers the flexibility needed in heterogeneous dynamic environments.

**A.12.4 eXtended Markup Language (XML).** The XML [Bray et al. ] model did not originate in the database community. It was introduced as an standard for exchanging information between Web applications. XML allows annotating data with information about its meaning rather than just its presentation [Vianu 2003]. From an abstract point of view, XML data are labeled ordered trees (with labels on nodes), where internal nodes define the structure and leaves the data (schema and data are mixed).

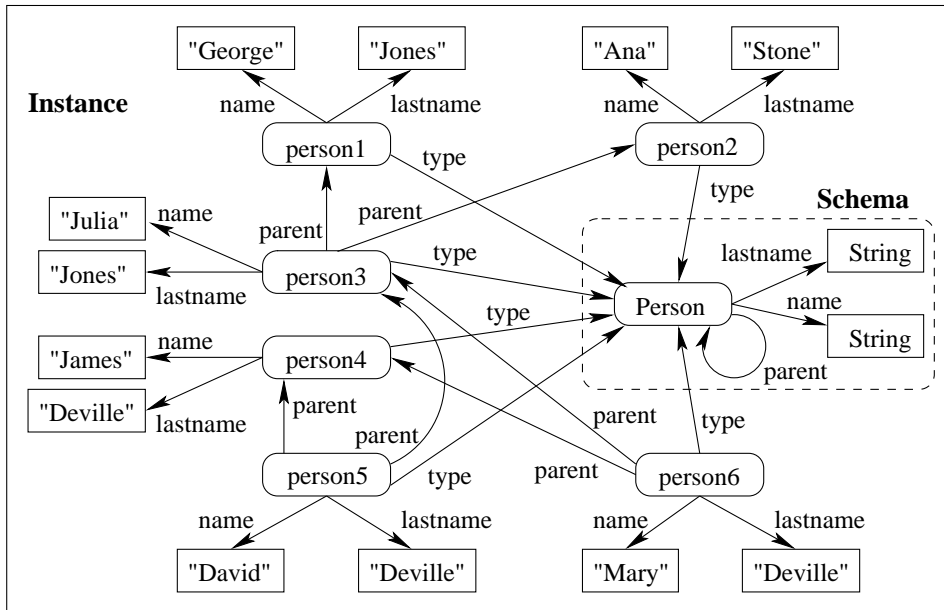

Fig. 18. RDF. Schema and instance are mixed together. In the example, the edges labeled *type* disconnect the instance from the schema. The instance is built by the subgraphs obtained by instantiating the nodes of the schema, and establishing the corresponding parent edges between these subgraphs.

Compared to graph data db-models, XML has an ordered-tree-like structure, which is a restricted type of graph. Nevertheless, XML additionally provides a referencing mechanism among elements that allows simulating arbitrary graphs. In this sense XML can simulate semistructured data. In XML, the information about the hierarchical structure of the data is part of the data (in other words XML is self-describing); in contrast, in graph db-models this information is described by the schema graph in a more flexible fashion using relations between entities. From this point of view, graph db-models use connections to explicitly represent generalization, compositions, hierarchy, classification, and any/other type of relations.

**A.12.5 Resource Description Framework (RDF).** RDF [Klyne and Carroll 2004] is a recommendation of the W3C designed originally to represent metadata. The broad goal of RDF is to define a mechanism for describing resources that makes no assumptions about a particular application domain, nor defines (a priori) the semantics of any application domain.

One of the main advantages (features) of the RDF model is its ability to interconnect resources in an extensible way. Thus, RDF models information with graph-like structure, where basic notions of graph theory like node, edge, path, neighborhood, connectivity, distance, degree, etc., play a central role.

An atomic RDF expression is a triple consisting of a subject (the resource being described), a predicate (the property) and an object (the property value). Each triple represents a statement of a relationship between the things that it links. A

general RDF expression is a set of such triples, which can be intuitively considered as a labeled graph, called an RDF Graph [Klyne and Carroll 2004], which formally is not a graph [Hayes and Gutierrez 2004] (see example in Figure 18).

Currently there is research work on storing information expressed in RDF, but none of these works define a graph db-model or even a db-model. In addition several languages for querying RDF data has been proposed and implemented, which follow the lines of database query languages like SQL, OQL, and XPath. A discussion of aspects related to querying RDF from a graph database perspective is presented in [Angles and Gutierrez 2005].

SPARQL [Prud'hommeaux and Seaborne 2005] is a proposal of Protocol and Query Language designed for easy access to RDF stores. It defines a query language with a SQL-like style, where a simple query is based on query patterns, and query processing consists of binding of variables to generate pattern solutions (graph pattern matching).
